1 INTRODUCTION

B[e] stars are enigmatic objects. Their optical spectra show strong Balmer emission lines as well as permitted and forbidden emission lines of lowly-ionized metals. In addition, B[e] stars display a near- and mid-infrared excess that is attributed to hot and warm circumstellar dust. However, because the definition of the B[e] class is purely morphological, it contains objects that are physically very different in terms of their initial mass and evolutionary phase: B[e] supergiants (B[e]SGs), Herbig AeBe (HAEeBe) stars, compact planetary nebulae, and symbiotic objects (e.g., Lamers et al. 1998). Especially B[e]SGs and HAeBe stars are difficult to distinguish; they have dense, cool, and dusty equatorial disks, which are related to either accretion and disk winds (in the case of HAeBe stars) or equatorially enhanced stellar winds (B[e]SGs). These disks give rise to molecular emission such as the first overtone bands of carbon monoxide (CO) in the near-infrared which are observed in both HAeBe stars and B[e]SGs (Bik et al. 2006, McGregor et al. 1988, Morris et al. 1996). In addition, the position of HAeBe stars in the empirical Hertzsprung-Russell diagram overlaps with that of the low-luminosity B[e]SGs.

So far, comprehensive studies of B[e] stars, focused on the spectral classification and characterization, were mostly based on...
optical spectra. The last two decades new instruments have given access to the infrared (IR) spectral range and allowed high-quality spectra with the necessary spectral resolution to be obtained. But only now projects are checking systematically how appropriate spectral classification based on IR spectra alone is for general application purposes. For example, Oksala et al. (2013) find that based on K-band spectra three distinct groups of stars can be identified: (1) “regular” Be SGS with the expected spectrum of emission lines including the Pfund series and CO in emission, (2) S Dor-like luminous blue variables (LBVs) with a variety of strong emission lines but lacking the expected circumstellar CO emission, and (3) a group of cool stars, consisting of LBVs in outburst and Yellow Hypergiants (YHGs), showing the Pfund series in absorption.

The CO bands can be used to obtain an age estimate for a star. As proposed by Kraus (2009), stellar evolution models with rotation predict the enhancement of the carbon isotope $^{13}$C on the stellar surface during the core-hydrogen burning of massive stars through mixing. Via mass loss, it is transported into the circumstellar environments and locked into CO molecules. Hence, in evolved stars (i.e., supergiants), the enriched isotope should become detectable as CO bands. This was confirmed by detection of $^{13}$CO emission in known, extra-galactic S Dor-like luminous blue variables (LBVs) with a variety of strong emission lines but lacking the expected circumstellar CO emission, and (3) a group of cool stars, consisting of LBVs in outburst and Yellow Hypergiants (YHGs), showing the Pfund series in absorption.

We have embarked on a mini-survey of a galaxy of Be-like stars to investigate their evolutionary status and characterize their age and circumstellar material from K-band spectra. We present our observations in Sect. 3 with the results of the spectral analysis following in Sect. 4. The final part of the paper is dedicated to the discussion and conclusions of our findings (Sects. 4 and 5).

## 2 OBSERVATION AND DATA REDUCTION

Our sample stars (cf. Table 1) were observed with the Large Binocular Telescope (LBT) in Arizona, USA, during 3 runs in November 2010, April and May 2011. We used the LBT-LucI spectrograph (Seifert et al. 2003) to obtain seeing-limited, high-quality, long-slit spectra with the N1.8 camera, a slit width of 0.5′, and the K-band filter (1.93–2.48 μm) with the 210 μm grating tilted to center on $\lambda = 2.24 \mu m$ to have best wavelength coverage for the CO bands redwards of 2.29 μm. The resulting spectra have a spectral resolution of about $R = 6,100$ and a signal to noise ratio of S/N≈700.

Telluric standards were observed immediately before or after the science targets at similar airmass. B main-sequence stars were used as standard stars, to avoid the contamination of the CO bands with intrinsic features from a B supergiant or solar-type standard star. Table 1 lists the details of the observations.

Additional data for MWC 84 were obtained during April, 2011 and October, 2013 with GEMINI/GNIRS (programs GN-2011B-Q-24 and GN-2013B-Q-11) in high-resolution mode ($R=18,000$), using the 110.5 l/mm grating, the long camera (0.05″/pix), and the 0.10″ slit. We obtained spectra in the K-band (2.28–2.34 μm) centered on $\lambda = 2.31 \mu m$ to cover the first two CO bandheads.

Data sets from both telescopes were reduced using standard IRAF routines for long-slit spectroscopy including removal of cosmic rays and dead pixels, dark frames, division by a normalized flat field, distortion correction, and wavelength calibration. Sky subtraction was done by subtracting offset frames per target (AB pattern) correspondingly before the spectra extraction.

The frames of the telluric standard stars were treated in the same way. We produced calibration curves as the ratio of the extracted standard star spectra and Kurucz models (corresponding to the spectral types of the standard stars, Kurucz 1993) scaled to the stars’ 2MASS K-band magnitudes. As the Kurucz models do not reproduce the observed Br $\gamma$ line in the standard star spectra that part of the calibration curve was smoothed by linear interpolation between 2.15 and 2.17 μm. For flux calibration, the extracted science target spectra were divided by the corresponding calibration curves.

## 3 ANALYSIS AND RESULTS

The flux-calibrated spectra of the sample stars are presented in Fig. 1. Most spectra show more or less pronounced telluric residuals at about 2.316 and 2.370 μm. We attribute this to the not always perfect match of observing conditions between the science target and standard star.

For all sample stars we clearly detect the Brackett $\gamma$ line (Br $\gamma$, $\lambda 2.166 \mu m$) in emission. Additionally, iron (Fe II $\lambda 2.089 \mu m$) and a magnesium doublet (Mg II $\lambda 2.138/144 \mu m$) are detected. Three stars, MWC 314, MWC 84, and AS 381, also show features of the sodium doublet (Na I $\lambda 2.206/209 \mu m$) and helium (He I $\lambda 2.112 \mu m$) in emission. In Table 2, we list the measured equivalent widths of these lines for all stars.

Remarkably, MWC 314 is the only star whose spectrum shows very prominently lines of the Pfund series (see Fig. 1 top-most panel). Overall its spectral appearance is close to S-Dor-like Luminous Blue Variables (LBVs) and Be SGS (Oksala et al. 2013; a classification of MWC 314 as LBV will be discussed below (see Sect. 5)). Also, no molecular CO bands, neither in emission nor in absorption, are present in the spectrum.

However, CO bands are detected in the spectra of three stars: MWC 137 (in emission), MWC 623 and AS 381 (in absorption). Details of the spectra are shown in Figs. 4 and 5. MWC 137 displays $^{13}$CO in emission which shows that the star is evolved, i.e. possibly a Be SGS.

---

1 IRAF is distributed by the National Optical Astronomy Observatories, which are operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.
Both MWC 623 and AS 381 have been suspected to be binary stars; for MWC 623 Zickgraf & Stahl (1989) find a spectroscopic binary with two sets of spectral lines (SB2) and for AS 381 Miroshnichenko et al. (2002a) find neutral metal lines inferring a cool companion. Indeed, the spectra of both stars display CO absorptions which we attribute to a cool late-type companion, respectively. We measure the equivalent widths of the first band head (CO 2-0), see Table 2. Following González-Fernández et al. (2008, see Eqs. (5) and (6)), the equivalent width can be used to derive both the effective temperature and a spectral-type of the companion (the indicator \( G = 0 \ldots 5 \ldots 13 \) corresponds to spectral types K0 \ldots K5 \ldots M7).

For MWC 623 we find a K4 companion (\( G = 3.2 \) to 5.1 corresponding to spectral types between K3 to K5) with an effective
temperature of $T_{\text{eff}} = 4030 \pm 100$ K. In the case of AS 381, we determine a spectral type of the companion of K0 ($G = 0.09$ to 0.20 corresponding to a spectral type K0) with an effective temperature of $T_{\text{eff}} = 4550 \pm 100$ K. Errors on the effective temperature are dominated by those given in Eq. 5 of González-Fernández et al. (2008). In both cases one can argue for the detection of weak $^{13}$CO absorptions in the spectra, indicating a slightly evolved giant or supergiant (luminosity class of II to I).

Both MWC 84 and MWC 300 do not show any Pfund lines or CO emission in their spectra. However, MWC 84 shows the strongest He I and MWC 300 the strongest Fe II and Br $\gamma$ lines in emission, of all the sample stars.

4 DISCUSSION

4.1 MWC 314 – a quiescent B[e]SG/LBV?

For high-mass stars, stellar evolution models predict a short transitional phase as LBV from the core hydrogen-burning OB star progenitors to the core helium-burning Wolf-Rayet stars (e.g. Maeder et al. 2008). During the LBV phase the stars undergo extreme mass loss events (“outbursts”) after or followed by a rather stable (“quiescent” or “dormant”) state and are often associated with circumstellar nebulae. In addition, significant variability in brightness and spectral appearance can be detected more readily in the outburst phase but also are present in the quiescent state.

For MWC 314 spectral, photometric, and polarimetric variability was found covering different periods, e.g. Miroshnichenko (1996), Wisniewski et al. (2000), Groh et al. (2007). A detailed spectral analysis by Miroshnichenko et al. (1998), finding photospheric lines for the first time, classified the star as B0 supergiant with $T_{\text{eff}} = 25,000$ K. Additionally, the authors present indications for a non-spherical wind and derive a distance of $d = 3.0 \pm 0.2$ kpc from radial velocity (RV) measurements. This makes MWC 314 one of the most luminous stars in the Milky Way with log $(L/L_\odot) = 6.1 \pm 0.3$ (Miroshnichenko et al. 1998).

Later studies find different (effective) temperatures, based on different indicators and methods, e.g. 26,700 K to 32,000 K (Cidale et al. 2001), 16,200 K (Carmona et al. 2010), 18,000 K (Lobel et al. 2013). At the same time, different studies report the rather stable photospheric appearance of MWC 314 in $UBVRIJHK$ filter observations with about 0.3 mag variability, e.g. Bergner et al. (1995), Miroshnichenko (1996) covering the time span from 1954 to 1995). This results in a conflicting situation to determine the spectral type and evolutionary state of MWC 314.

The star was first proposed as LBV candidate by Miroshnichenko (1996). In case the above listed temperatures reflect a real change over the last 20 years, MWC 314 would be rather similar to other LBVs (see Table 3), thus supporting the classification of MWC 314 as LBV candidate. In Fig 2 we show MWC 314 in the Hertzsprung-Russell diagram (HRD) among known Galactic LBVs and LBV candidates. It is located between the empirical Humphreys-Davidson limit (Humphreys & Davidson 1994, solid line in Fig 2) and the hot temperature LBV minimum light strip (Clark et al. 2005, dashed line in Fig 2).

In our spectrum of MWC 314 we find pronounced lines of hydrogen, Br $\gamma$ and Pfund series, and prominent emission lines of Fe II, Mg II, and Na I. Comparing the spectra of MWC 84, MWC 137, and MWC 314, we find most pronounced Na I and Mg II emission for the latter with remarkable line strengths. Typically, comparable line strengths are only found in late-type (F and G) supergiants (Hanson et al. 1996, Wallace & Hinkle 1997). In B-type emission-line stars these lines are usually (much) weaker, but with a slight trend for an increase towards later types (see Oksala et al. 2013). If we consider that the temperature obtained by Lobel et al. (2013) within the past years is the currently most reliable one, then we can assign MWC 314 a spectral type of B2 according to the temperature-spectral type relation for Galactic supergiant stars of Searle et al. (2008).

Previous studies by Muratorio et al. (2008) found indications for a quasi-Keplerian circumstellar disk from double-peaked emission lines. We do not detect any significant IR excess that one would expect from warm/hot dust in the circumstellar disk; this result is highly indicative for the absence of such dust. We also do not find any CO emissions or absorptions. This is comparable to other LBV candidates where the lack of CO emission has been attributed to the circumstellar material having too low a density (Morris et al. 1996, Oksala et al. 2013).

The presence of a dense and compact gas disk in MWC 314 can be concluded from the detection of double peaked [Ca II] emission together with the non-detection of [O I] by Aret et al. (in preparation). Aret et al. (2012) show, that [Ca II] traces regions of higher densities, i.e. closer to the star. Thus the lack of [O I] in MWC 314 must be attributed to a dense but compact disk. On the other hand, the presence of the strong emission from neutral sodium, which has a very low ionization potential, indicates the existence of a second very dense, but cool region of circumstellar material. To allow for the emission of Na I, that region should be shielded from direct stellar radiation. In a spherically-symmetric stellar wind, too high densities would be required. But in such a high density environment the emission of [O I] can be expected. Hence, it seems more logical to assume that the Na I emission arises from a cool circumstellar disk (or ring), which provides ideal shielding conditions (e.g. Scoville et al. 1983, McGregor et al. 1984). However, at

2 A disk in Keplerian rotation displaying simultaneously a small outflow component, see e.g. Krtiˇ cka et al. (2011), Kurfürst et al. (2013).
from the environment of the companion. Known LBV stars, that bipolar nebulae might be linked to a possible binary nature of these stars. For MWC 314 the binary status is still under debate. Early reports of photometric variations were interpreted as being more consistent with the pulsations of a slightly evolved supergiant rather than being attributed to a binary companion. However, recent studies continue the ambiguity of the binary status, e.g. Rossi et al. (2011) cannot detect any periodic RV variations. However, Lobel et al. (2013) find variations with a period of P = 60.7 d (and an orbital eccentricity of e = 0.26), inferring a massive, possibly evolved supergiant companion to MWC 314. Our spectrum does not show any CO absorption indicative for cool companions. Thus K and M-type companions can be excluded for MWC 314. However, a massive companion as suggested by Lobel et al. (2013) cannot be ruled out. Further high-resolution spectroscopy and/or spatially-resolved imaging is necessary to confirm or contradict the binary suspicion.

4.2 MWC 137 - a B[e]SG candidate with $^{13}$CO emission

This star is a typical example for the difficulty to distinguish B[e]SG and HAeBe stars. Based on the preferred distance estimate, the star has been considered to be a young unevolved object, e.g. a Pistol star. A study by Marston & McCollum (2008) found a bipolar nebula around MWC 314 that is similar in morphology to the one around η Car. Their results are not conclusive whether or not that nebula was ejected in a past LBV outburst or not.

Recently, it has been discussed for a large fraction of the known LBV stars, that bipolar nebulae might be linked to a possible binary nature of these stars. For MWC 314 the binary status is still under debate. Early reports of photometric variations were interpreted as being more consistent with the pulsations of a slightly evolved supergiant rather than being attributed to a binary companion. However, recent studies continue the ambiguity of the binary status, e.g. Rossi et al. (2011) cannot detect any periodic RV variations. However, Lobel et al. (2013) find variations with a period of P = 60.7 d (and an orbital eccentricity of e = 0.26), inferring a massive, possibly evolved supergiant companion to MWC 314. Our spectrum does not show any CO absorption indicative for cool companions. Thus K and M-type companions can be excluded for MWC 314. However, a massive companion as suggested by Lobel et al. (2013) cannot be ruled out. Further high-resolution spectroscopy and/or spatially-resolved imaging is necessary to confirm or contradict the binary suspicion.

the authors argue that the small photometric variations but stable conclusion that the star should be classified as B[e]SG. In addition, Esteban & Fernandez (1998) find the associated ring nebula B[e]SG rather than a HAeBe star (see also Zickgraf 1992). More-spectral line profiles found for MWC 137, indicate the star being a scale star-forming region as might be expected for an HAeBe star.

In contrast these authors remark the spectroscopical resemblance of the nebula to those observed around LBVs or Wolf-Rayet stars (Esteban & Fernandez 1998 and references therein).

Marston & McCollom (2008) confirm the ring nebula and in addition find a bipolar structure in their narrow-band images. However, the nebula material seems chemically unprocessed which might indicate that the circumstellar material either is swept-up interstellar matter or was ejected during an early stellar-evolution phase.

MWC 137 was listed by Miroshnichenko (2007) as FS CMa candidate star which implies that it is a binary system. However, neither Baines et al. (2006) nor Wheelwright et al. (2010) found evidence for the binary status of MWC 137 from their spectro-astrometric observations (a method sensitive down to about 100 mas binary separation, e.g. Bailey 1998). HIPPAR-COS data suggest that MWC 137 is an astrometric binary (Makarov & Kanlan 2005), possibly with a white dwarf or subdwarf companion (Lanning & Lépine 2006).

In our spectrum (see Fig[1]), we do not find indications for a cool companion in terms of CO absorption or a set of emission or absorption lines accountable to a hot main-sequence companion; instead, a closer look at our spectrum shows prominent CO bandheads in emission, both of $^{12}$CO and $^{13}$CO. In Fig[2] we over-plot a model combining CO and Pfund emission added to the observed continuum. The model was computed using the codes of Kraus et al. (2000), Kraus (2009) and Oksala et al. (2013); parameters of the Pfund and CO emitting regions as obtained by Oksala et al. (2013). The excellent agreement of the model and the observations confirms the results by Oksala et al. (2013). In particular the presence of clearly detectable emission from $^{13}$CO implies that the circumstellar material is enriched in the $^{13}$C isotope. This excludes a pre-main sequence nature according to the stellar evolution models by Ekström et al. (2012) and MWC 137 has to be classified as evolved, post-main sequence object.

### 4.3 B[e] supergiant candidates

In two further stars of our sample, MWC 300 and MWC 84, we do not detect CO emission in their spectra. However, in the following we summarize the evidences for their classification as B[e]SG:

MWC 300 According to Appenzeller (1977) this star is classified as B1 Ia. Miroshnichenko et al. (2004) detect photospheric lines and their spectral analysis indicates the supergiant status of the star, with $T_{\text{eff}} = 20,000$ K. From comparison of equivalent-width measurements they derive a luminosity of $\log (L/L_\odot) = 5.1 \pm 0.1$ assuming a distance of $d = 1.8 \pm 0.2$ kpc. RV variations (Miroshnichenko et al. 2004) and a clear signal from spectro-astrometry (Takami et al. 2003) suggest that MWC 300 is a binary. From near-infrared interferometry, Wang et al. (2012) find evidence for a dusty circumstellar (maybe even circumbinary) disk and a binary companion at a projected separation of about 7.9 AU. No extended circumstellar material has been detected in H$\alpha$ imaging by Marston & McCollom (2008).

Our spectrum shows a clear infrared excess that we attribute to the circumstellar/circumbinary dust, but we do not detect CO emission. As for MWC 314, this might indicate that the material’s density is too low to give rise to molecular emission. In addition, we don’t find evidence for a cool companion by the lack of CO absorption expected for late-type stars. As Miroshnichenko et al. (2004) suggests a companion of about 6 $M_\odot$, i.e. a B-type star, we scanned the spectrum for the expected hydrogen absorption lines with no result. This might indicate a supergiant companion for which the spectral lines are less pronounced, such that basically only a contribution to the continuum flux might be considered. Interestingly,
models of Wang et al. (2012), fitted to their interferometric data, suggest the two binary components to be about similar in effective temperature and to have a brightness ratio of about 2.2.

MWC 84 Also known as Cl Cam, MWC 84 had a spectacular outburst in March 1998, detected from γ-rays to radio emission (e.g. Clark et al. 1999, Robinson et al. 2002). Hynes et al. (2002) classified the star as spectral type B0-B2, finding its emission-line spectrum typical for a Be[S]G. The authors refer to the star as an atypical high-mass X-ray binary but speculations about the existence and nature of the compact companion are ongoing. Hellming et al. (1998) describe the star as X-ray binary/ X-ray transient radio source, and detect a slow, decelerating shell in radio emission. However, the nature of this emission is also still under debate (e.g. Rupen et al. 2003). In addition, a faint circumstellar shell has been detected by Marston & McCollum (2008), but the authors find no clear evidence to determine whether this is stellar ejecta or the illuminated local interstellar material.

The analysis of spectral line profiles, the derived extinction, and interferometric observations suggest that MWC 84 has an equatorial disk wind with a dust-free high-temperature zone close to the star, and that it is viewed almost pole-on (e.g. Thureau et al. 2009, Hynes et al. 2002, Miroshnichenko et al. 2002b). The latter authors revised the distance estimate based on RV measurements and interstellar Na I D-lines, to about 2.2 kpc, placing the star in the Perseus arm; with that distance, an upper-limit luminosity of $\log L/L_\odot < 4$ is derived. Other studies find both smaller ($d = 1.1 - 1.9$ kpc by Barsukova et al. 2006, Clark et al. 2000, $\approx 2$ kpc) and larger (e.g. $d \approx 5$ kpc Robinson et al. 2002) distances, hampering reliable estimates of the luminosity.

Clark et al. (1999) present $J$, $H$ and $K$-band spectra obtained one month after the outburst that are rich in hydrogen, helium and iron emission lines and clearly show lines of the Pfund series and the presence of CO emission in the K-band. The authors argue that the molecular emission likely arises due to collisional excitation from regions shielded from the stellar radiation, which requires high densities. In addition, Clark et al. (2000, covering 1998 to 1999) and Thureau et al. (2009, data for 2004 and 2005) present $UBVRIJHK$ photometry showing that the star is slightly brighter than in pre-outburst state, but rather stable over the long time range of seven years. Also near-infrared interferometric data (Thureau et al. 2009, covering 1998 to 2006) have supported the scenario of a stable circumstellar disk in the last decade.

Our spectra (see Fig. 4) do not show any indication of Pfund lines or CO emission or absorption, neither in 2010 (LBT-Luci1) nor in 2011 or 2013 (both Gemini-GNIRS). We attribute this disappearance of Pfund and CO emission to the loss/dilution of the high-density circumstellar material and the return of MWC 84 to its pre-outburst stage.

4.4 Unclassified B[e] stars

For both MWC 623 and AS 381, it has been suggested that the stars are in binary systems with a cool companion. Our finding of prominent CO absorption bands supports this position and we determined the spectral types for the companions from the CO band head equivalent widths, see Sect. 4.4 and Table 3.

MWC 623 Based on the detection of a set of early-type (emission) and late-type (absorption) optical lines, Zickgraf & Staahl (1989) conclude that MWC 623 is a spectroscopic binary (SB2) of type B2+K2. However, they find no indication for RV variations, attributing this to a binary period longer than covered by their range of observational data of 2 years. Zickgraf (2001) reclassifies the spectral types of the binary components to B4III+K2 II- Ib but no periodic RV variations are found even in long-time observations (Zickgraf 2001, Polster et al. 2013). This might indicate a pole-on orientation of the system, e.g. Miroshnichenko (2006).

Based on the K star’s luminosity class, Zickgraf (2001) derives a spectroscopic distance of $d = 2.4$ kpc. Our derived spectral type of the cool component is a slightly cooler K4-I I star, but with the same range for the luminosity class. We take MWC 623’s 2MASS magnitude $K_S = 5.38$ mag and assume that the $K$-band emission is dominated by the cool companion. With the distance and reddening as listed in Table 4 and bolometric corrections determined following Levesque et al. (2005), we derive the companion’s luminosity as $\log (L/L_\odot) = 3.61$. Assuming that MWC 623 is a physical long-period binary and not a chance superposition detected in the spectrum, each component in all likelihood has evolved like a single star. From comparison with the stellar-evolution track of $7 \ M_\odot$ initial mass (see Fig 7), we find an age difference of 1.8 Myr of the components. This seems negligible compared to the total age of the system of about 50 Myr.

AS 381 The star was first listed in the Hα surveys by Merrill & Burwell (1951) and Henize (1974) as emission-line star. Thé et al. (1994) classify it as Be star with IR excess. Miroshnichenko et al. (2002) detected absorption lines of neutral metals in their near-IR spectra and $^{12}$CO absorption bands, concluding that the star is a B1 + K binary system. The authors also derive a lower limit for the orbital period of $P \approx 30$ d. They estimate the distance to be $d = 4 \pm 1$ kpc deriving luminosities of $\log (L/L_\odot) = 4.9$ and $\log (L/L_\odot) = 3.6$ for the B and K component, respectively. In addition, the authors claim to find signs of ongoing mass transfer between the binary components. Miroshnichenko (2007) lists an effective temperature of $T_e \approx 21000 \ K$, a brightness ratio of about 2.2. Within the errors, this result is robust enough to allow up to 25% of the $K$-band flux to be contributed from the B-type companion.

According to the stellar evolution tracks in Fig 7, we derive a spectral type of K0 for the companion from the equivalent width measured for the first $^{12}$CO bandhead. However, the determination of the luminosity class is not that unambiguous, as a clear detection of $^{12}$CO is not confirmed.

Assuming that the flux in the infrared-wavelength range is dominated by the cool companion, we use the mean $K$-band magnitude of those listed by Miroshnichenko et al. (2002) (cf. Table 2), $K = 6.58$ mag, to derive the companion’s luminosity. Including the distance and reddening as listed in Table 4 and the bolometric corrections for the $K$-band according to Levesque et al. (2005), we obtain $\log L/L_\odot = 3.94 \pm 0.10$. Within the errors, this result is robust enough to allow up to 25% of the $K$-band flux to be contributed from the B-type companion.

According to the stellar evolution tracks in Fig 7, we determine lower-limit initial masses of about $16 \ M_\odot$ and $10 \ M_\odot$, and ages of about 13 Myr and 25 Myr for the B-type and K-type star, respectively. Fig 7 also suggests that the B component of AS 381, although more massive, seems to be less evolved than the K companion. Given the short lower-limit orbital period of the system, it seems possible to consider that mass transfer might have happened at some stage of the evolution of this binary star. In that case single-star stellar evolution models are of course not adequate for mass and age determination.
We conducted a mini-survey of Galactic B[e] stars with the LBT-Luci I and Gemini-GNIRS to characterize their near-infrared K-band spectra. The most dominant emission line feature detected is the Brγ line that is present in all our sample stars. In many cases, iron and magnesium emission can be identified, while helium and sodium emission lines are less common. In addition, the detection and analysis of molecular lines like from carbon monoxide is a very helpful and powerful tool for the classification of the stars and their circumstellar material, or for the confirmation of a cool companion respectively.

Summarizing the results of our B[e] survey:

(i) MWC 314 shows a spectrum rich in lines of hydrogen, including pronounced lines of the Pfund series. Several lines of CO bands in emission in the spectrum of MWC 314 strongly resemble the ones of LBV stars. An excess is detected and CO emission is lacking at all. The K-band spectrum of MWC 314 strongly resembles the ones of LBV stars and candidates, e.g. S Dor and LHA 120-S 127. Tracers for circumstellar material indicate the presence of a non-continuous gas disk, i.e. rings, around MWC 314. We determine a spectral type of B2 and an age of about 6 Myr; with a lower-limit initial mass of 40 M⊙ it’s the most luminous and most massive star in our sample.

(ii) We detect 12CO bands in emission in the spectrum of MWC 137 indicating an evolved nature of the star. However, the classification of MWC 137 as Galactic supergiant B[e] star has to be confirmed with more data.

(iii) MWC 84 shows prominent He I line emissions. After an outburst event in 1998, circumstellar material was clearly and stable detected over decades, e.g. Pfund lines and CO emission. We observed the star at different epochs with LBT-Luci I and Gemini-GNIRS to characterize their near-infrared K-band spectra.

(iv) MWC 623 and AS 381-a show prominent CO(2-0) line emissions. After an outburst event in 1998, circumstellar material was clearly detected over decades, e.g. Pfund lines and CO emission. We observed the star at different epochs with LBT-Luci I and Gemini-GNIRS to characterize their near-infrared K-band spectra.

(v) MWC 623-b and AS 381-b show prominent CO(2-0) line emissions. After an outburst event in 1998, circumstellar material was clearly detected over decades, e.g. Pfund lines and CO emission. We observed the star at different epochs with LBT-Luci I and Gemini-GNIRS to characterize their near-infrared K-band spectra.

Parameters given in italic are from this work, others according to the indicated references: (1) Carmona et al. (2013), distance and E(B − V), (2) Miroshnichenko et al. (2002a), (3) Zickgraf (2001), (4) Miroshnichenko et al. (2002b), (5) Hynes et al. (2002), (6) Miroshnichenko et al. (2004), (7) Esteban & Fernandez (1998), (8) Lobel et al. (2013) age estimates derived by comparison with single star evolution models (Ekström et al. 2012), see Fig. 5 and discussion of individual stars for further details.

Figure 6. Detail of the spectra of MWC 623 and AS 381 showing the CO absorption attributed to their cool companions.

Figure 7. HRD for MWC 623 and AS 381 and their cool companions; single star stellar evolution models for different initial masses by Ekström et al. (2012) accounting for the effects of stellar rotation.
GNIRS and no signs of a recent prominent eruption was found during 2010 and 2013. Moreover, the observations reveal the disappearance of the circumstellar Pfund lines and the CO emission.

(iv) MWC 300 is a B[e] supergiant candidate in a binary system. Its spectrum does not show CO emission or absorption at the time of observation.

(v) CO absorption bands are found in the spectra of MWC 623 and AS 381. Both stars have been suspected to be binary systems previously. Attributing the observed CO absorption to cool companions, we find a spectral classification of B4-II + K4-I-II (MWC 623) and B1 + K0-I-II (AS 381) and derive the fundamental stellar parameters of the companions.

All sample stars are slightly evolved (ages of 6 to 50 Myr) with progenitor masses in the intermediate to high-mass range (7 to 40 $M_\odot$). In the cases of binary stars and candidates, episodes of mass transfer might have to be considered in the evolution of the components, thus hampering the exact characterization of the systems. Future observations, for example radial velocity variations, pronounced variability, and higher spectral resolution might be needed to ultimately confirm the binary companions.

Particularly, MWC 84 and MWC 300 might be considered as binary supergiant B[e] candidates in a quiescent transition phase, showing very low densities in their circumstellar envelopes to sustain molecular lines. Unfortunately, some supergiant B[e] stars cannot be distinguished as unambiguously as expected (Oksala et al. 2013) and further observation are needed to clarify the evolutionary status of these stars.

ACKNOWLEDGMENTS

The authors thank Jochen Heidt for useful discussions about planning the observations and valuable help in preparing the observing scripts; Steve Allenson and the LBTO team for the support during the observing runs at the LBT. We thank our referee A. Miroshnichenko for valuable comments that helped to improve this manuscript.
